MoSe2 as one of the two-dimensional (2D) ultrathin transition metal dichalcogenides (TMDCs) emerged as a promising alternative of graphene for nano-electronic and opto-electronic devices [1–6]. It exhibits unique electronic and optical properties such as an intrinsic band gap [7–10], strong photoluminescence (PL) [11] and efficient photovoltaic (PV) response [12, 13]. In contrast to an indirect gap ~1.1 eV in bulk MoSe2, the monolayer MoSe2 exhibits direct bandgap of ~1.55 eV [7]. The unique electronic/optical properties and atomic-thickness make it promising for flexible nano-electronic applications such as switchable transistors [11, 14], photodetectors [12], ultrathin PV devices [10, 13], as well as thermoelectric applications [15, 16]. In addition, ultra-thin nanosheets of MoSe2 show a room-temperature mobility of ~50 cm² V⁻¹ s⁻¹ [14], which increases almost four-fold when the temperature decreases to 78 K. Therefore, the monolayer MoSe2 becomes the promising material in next-generation ultrathin nano-electronic devices. However, inefficient thermal management may become challenging for the performance and reliability of ultrathin nano-electronic devices as the device dimension scales down and power increases. Phonons are expected to be the dominant energy carriers for the thermal transport in 2D TMDs [6, 17–19]. A fundamental understanding of phonon transport properties of the monolayer MoSe2 is of great importance for improving reliability and energy efficiency of the MoSe2-based devices.

MoSe2 as one of the two-dimensional (2D) ultrathin transition metal dichalcogenides (TMDCs) emerged as a promising alternative of graphene for nano-electronic and opto-electronic devices [1–6]. It exhibits unique electronic and optical properties such as an intrinsic band gap [7–10], strong photoluminescence (PL) [11] and efficient photovoltaic (PV) response [12, 13]. In contrast to an indirect gap ~1.1 eV in bulk MoSe2, the monolayer MoSe2 exhibits direct bandgap of ~1.55 eV [7]. Phonons are expected to be the dominant energy carriers for the thermal transport in 2D TMDs [6, 17–19]. A fundamental understanding of phonon transport properties of the monolayer MoSe2 is of great importance for improving reliability and energy efficiency of the MoSe2-based devices. A recent theoretical study reported a relatively low thermal conductivity of monolayer MoSe2 (54 W mK⁻¹ at room temperature) compared to other 2D TMDs by solving Peierls–Boltzmann transport equation (PBTE) calculations [17]. A much lower thermal conductivity of 17.6 W mK⁻¹ is obtained using Slack model [20, 21]. In addition, due to the imperfection of growth processes, the crystal lattice...
of monolayer TMDs contains unintentional localized defects such as vacancies [22–26], dislocation cores and grain boundaries [27] which could further suppress the thermal transport [28, 29]. Peng et al. found that the defect-induced quasi-localized phonon states have a significant influence on reducing the thermal conductivity of MoS$_2$ from the first-principles calculations [28]. Ding et al. used non-equilibrium molecular dynamics simulations to demonstrate that thermal conductivity of monolayer MoS$_2$ can be effectively tuned by introducing phonon–defect scattering [29]. However, very few studies has focused on exploring the effect of defects on the thermal transport in monolayer MoSe$_2$. The defect engineering for Selenium vacancies in the monolayer MoSe$_2$ can provide promising opportunities for tailoring its properties for various device applications [30–32]. Isoelectronic doping is one of the most effective strategies to suppress or to manage the vacancy concentration [33] and precisely tailor its properties for desired applications, such as enhancing the PL, modulating the carrier type and raising the properties for desired applications, such as enhancing vacancy concentration [33] and precisely tailoring its properties for various device applications [30–32].

In this letter, we use first-principle density functional theory (DFT) along with the phonon Boltzmann transport equation (BTE) to study the phonon transport properties of monolayer MoSe$_2$ considering the effects of scattering by the boundary, defects, and doping. The effect of sample size on thermal conductivity at different temperatures is studied along with the influence of Se vacancies. The model for estimating the effect of Se vacancies on phonon properties of the monolayer MoSe$_2$ is developed by considering contributions of two different types of the defect-induced phonon scatterings: one caused by the missing mass of the Se atoms, the other caused by the change of force constants between the under-coordinated atoms near the vacancies. To further illustrate how the Se vacancies affect the phonon transport in the monolayer MoSe$_2$, we investigate the phonon property of the monolayer MoSe$_2$ with 16.7% W doping. This percentage W doping is selected for the present study because samples with such percentage of doping has been fabricated and Se vacancy suppression has been demonstrated in [24, 36]. We find that the W doping could enhance the thermal transport of the pristine monolayer MoSe$_2$ if the boundary scattering is ignored, i.e. for large size samples. However, the W doping in the defective MoSe$_2$ amplifies the influence of the phonon scattering caused by the Se vacancies, which results in a further decrease in thermal conductivity of monolayer MoSe$_2$ with Se vacancies.

Total energy calculations are based on the first-principles DFT as implemented in the Vienna ab initio simulation package (VASP) [37]. A plane-wave basis set and the projector augmented-wave (PAW) method are used with Perdew, Burke, and Ernzerhof (PBE) exchange-correlation functional [38–40]. The kinetic energy cutoff of the supercell is 500 eV. The system energy convergence criterion is set to be $10^{-9}$ eV. The force convergence criterion is set to be $0.01$ eV Å$^{-1}$. The structure of monolayer MoSe$_2$ shown in figure 1(a) is optimized with an $18 \times 18 \times 1$ grid for Brillouin zone sampling. An 18 Å vacuum space along the z-axis is used to eliminate the interaction emerging from the periodic boundary condition. The lattice constant of the monolayer MoSe$_2$ is obtained with the value of 3.32 Å, which is in good agreement with the theoretical result of 3.32 Å [17], and the experimental result of 3.30 Å [41]. Using this optimized lattice constant, the $6 \times 6$ and $4 \times 4$ supercells of monolayer MoSe$_2$ with $3 \times 3 \times 1$ k-point grid are assembled for the calculations of the second-order harmonic and third-order anharmonic interatomic force constants (IFCs), respectively. The displacement length of each atom from its equilibrium position is 0.01 Å. The interactions between atoms up to the 4th nearest neighboring shell are taken into account for the third-order IFCs calculation. Using the second-order and third-order IFCs obtained from the first-principles calculations, the phonon relaxation times and thermal conductivities of monolayer MoSe$_2$ can be calculated using Fermi’s Golden rule [42] with the relaxation time approximation (RTA) and the iterative solution of the BTE [19, 43–45] (see section A in the supporting information (stacks.iop.org/TDM/5/031008/mmedia)). In addition, following the Matthiessen’s...
we calculate the size-dependent thermal conductivity at different temperatures by combining the phonon scattering due to anharmonicity and size effect \([47, 48]\). Furthermore, we consider the effects of Se vacancies in the monolayer MoSe\(_2\) on the phonon scattering rate and thermal conductivity by adding two different types of the defect-induced phonon scattering to the total phonon scattering rate:

\[
\frac{1}{\tau} = \frac{1}{\tau_{\text{anh}}} + \frac{1}{\tau_b} + \frac{1}{\tau_V} + \frac{1}{\tau_F} 
\]

(1)

where \(\frac{1}{\tau_{\text{anh}}}\) and \(\frac{1}{\tau_b}\) are the intrinsic anharmonic phonon scattering rate and phonon boundary scattering rate, respectively. \(\frac{1}{\tau_V}\) is the scattering rate caused by the missing mass of the Se atom in the crystal, and \(\frac{1}{\tau_F}\) is the scattering rate caused by the change of force constants between the under-coordinated atoms near the vacancies. They can be expressed as \([49-52]\),

\[
\frac{1}{\tau_V} = x\left(\frac{-M_V}{M} - 2\right) \frac{\pi \omega^2 g(\omega)}{2} 
\]

(2)

\[
\frac{1}{\tau_F} = x\left(\frac{\delta C}{C}\right) \frac{4\pi \omega^2 g(\omega)}{G} 
\]

(3)

where \(x\) is the density of vacancies, \(M\) is the average mass per atom, \(M_V\) is the mass of the missing atom, \(g(\omega)\) is the phonon density of states (DOSs), \(G\) is the number of atoms in the crystal and \(C\) is the force constant.

Figure 2(a) presents the size-dependent thermal conductivity of monolayer MoSe\(_2\) at different temperatures. Results show that the phonon boundary scattering has a significant influence on the thermal conductivity if the sample size is smaller than 1 \(\mu\)m. Below that size, most of the phonons will have a higher probability to hit the boundary before they scatter with other phonons \([19]\). While the size effect can be ignored if the sample size is larger than 10 \(\mu\)m since the maximum phonon mean free path in MoSe\(_2\) is around 10 \(\mu\)m. Furthermore, the boundary effects also play a significant role in the thermal conductivity at the low temperature. It is because the strength of the Umklapp three-phonon process \([53]\) at low temperatures is relatively weak and the phonon boundary scattering becomes much more dominant in the phonon transport process. On the other hand, at high temperatures (>800 K), the size effect can be ignored because the phonon transport is dominated by the strong Umklapp process.

Besides the boundary effects, defects also have a significant impact on the thermal conductivity of monolayer MoSe\(_2\). Figures 2(b) and (c) shows the temperature-dependent thermal conductivity and phonon lifetime of monolayer MoSe\(_2\) with Se vacancies. The calculations are based on the sample size of 2 \(\mu\)m. Results indicate that 1%, 2% and 4% Se vacancies in the monolayer MoSe\(_2\) significantly reduce the thermal conductivity.
vacancies decrease the thermal conductivity of monolayer MoSe$_2$ by 27.7%, 39.5% and 51.9%, respectively, at room temperature. In our model (equations (2) and (3)), the effect of Se vacancies in crystals on phonon transport is treated by perturbation theory, i.e., contribution to the phonon scattering rate by two different types of the defect-induced phonon scatterings. One corresponds to the missing mass of the Se atoms, which implies the removal of the kinetic energy and potential energy. The other corresponds to the change in force constants between the under-coordinated atoms near the vacancies. Both of these defect-induced phonon scattering increase the total phonon scattering rate and decrease the phonon lifetime in the entire frequency range (figure 2(c)). Furthermore, we also find that the defect-induced phonon scattering rate caused by the change of the force constants near the vacancies has more impact on the total thermal conductivity than that caused by the atom mass missing as shown in figure 2(d). We observe that Se vacancies have a weak impact on the thermal conductivity at high temperatures. It is because that the three-phonon scattering rates corresponding to anharmonicity become dominant at high temperatures and the scattering rates corresponding to the defect related terms, $1/\tau_V$ and $1/\tau_T$ in equation (1), have less contribution to the total phonon scattering rate.

In order to understand the influence of methods to suppress the defect concentration in the monolayer MoSe$_2$, we study the phonon transport property of MoSe$_2$ under the influence of the W doping. The structure of the W doped monolayer MoSe$_2$ used in this work is shown in figure 1(b), which is optimized with the same lattice constant as of monolayer MoSe$_2$. The concentration of W atoms is about 16.7%, which makes the W doped MoSe$_2$ as Mo$_{0.83}$W$_{0.17}$Se$_2$. The $2 \times 2$ supercell of monolayer MoSe$_2$ is assembled for the calculations of the second-order harmonic and third-order anharmonic IFCs. Figure 3(a) shows the temperature-dependent thermal conductivity of monolayer pristine MoSe$_2$ and W doped MoSe$_2$ with various sample sizes. We find that the W doping increases the thermal conductivity of monolayer pristine MoSe$_2$. In addition, the difference becomes larger as the temperature increases (figure 3(a)). To better understand the impact of W doping on the thermal conductivity of the pristine MoSe$_2$, we also calculated the size-dependent thermal conductivity of the monolayer MoSe$_2$ and the W doped MoSe$_2$, which is compared to that of the monolayer WSe$_2$ at 300 K (figure 3(b)). Results indicate that the thermal conductivity of W doped MoSe$_2$ is similar to that of the pristine MoSe$_2$ for sample sizes smaller than 1 $\mu$m. The phonon scattering from boundary effect has a greater impact on the thermal conductivity of the W doped MoSe$_2$ than that of the pristine MoSe$_2$. If we reduce the boundary scattering influence by considering large-size samples, the W doping could increase the thermal conductivity of pristine MoSe$_2$, e.g., 23.6% increase is observed for 10 $\mu$m sample (figure 3(b)). This indicates that for low sample size, boundary scattering effect is significant leading to similar conductivity but the intrinsic thermal conductivity of W doped MoSe$_2$ is higher than pristine MoSe$_2$ as observed in large-size samples.

To further understand it, we calculate the phonon dispersions of monolayer MoSe$_2$ and WSe$_2$ along $\Gamma-M$ direction which is shown in figure 4(a). As expected, all the phonon branches of WSe$_2$ are lower in frequency than that of MoSe$_2$ because of the mass difference between W and Mo atoms. In addition, a larger gap between the optical and acoustic phonon branches in WSe$_2$ (1.3 THz) is observed than that in MoSe$_2$ (0.21 THz). Due to the larger gap between optical and acoustic phonon branches of WSe$_2$, more energy is needed for the annihilation process of two acoustic phonon modes into one optical mode in WSe$_2$. As a result, probability of this type of phonon scatterings becomes less leading to the decrease of the Umklapp scattering strength in WSe$_2$ compared to the MoSe$_2$. Therefore, the thermal conductivity of the monolayer WSe$_2$ is larger than that of the monolayer MoSe$_2$. Introducing W atoms in the MoSe$_2$ results in thermal conductivity values between that of MoSe$_2$ and WSe$_2$. Furthermore, it can also be supported by the three-phonon scattering phase space in figure 4(b). It indicates the volume of phase space available for three-phonon scattering, which is another way to indicate the likelihood of phonons being scattered. The details of calculation are provided in the section B of the supporting information. The phase space of the monolayer MoSe$_2$ is larger than that of the Mo$_{0.83}$W$_{0.17}$Se$_2$ as expected from the smaller phonon frequency gap between optical and acoustic branches (figure 4(b)). In other words, the phonons in Mo$_{0.83}$W$_{0.17}$Se$_2$ will have fewer channels for three-phonon scatterings, which results in the relatively longer phonon relaxation time (figure 5(b)) and larger thermal conductivity.

What happens to the thermal conductivity of the monolayer MoSe$_2$ if there still exist defects such as Se vacancies after the W doping? In order to investigate the impact of the defects on the thermal conductivity of the W doped MoSe$_2$, we calculate the temperature-dependent thermal conductivity and phonon lifetime of the W doped MoSe$_2$ with Se vacancies (figures 5(a) and (b)). Results indicate that after 16.7% W doping, the existence of 1%, and 2% Se vacancy concentration decreases the thermal conductivity of the monolayer MoSe$_2$ by 34.0%, and 46.2%, respectively, at room temperature. Compared with the 27.7%, and 39.4% decrease of the thermal conductivity of monolayer MoSe$_2$ with the same Se vacancy concentration, we find that the introduction of W atoms in the defective MoSe$_2$ amplifies the influence of the phonon scattering caused by the Se vacancies, which results in a further decrease in thermal conductivity compared to that of monolayer MoSe$_2$ with defects. For example, the W doping suppresses the Se-vacant sites by 50% (from 4% to 2%). The thermal conductivity of the 2%
defective W doped MoSe₂ is just 1.4% higher than that of 4% defective monolayer MoSe₂, figure 5(a). However, if the doping process makes the 2% Se-vacant MoSe₂ into the W doped MoSe₂ with no Se vacancies, the thermal conductivity can be increased dramatically by more than 80%.

To further illustrate why the introduced defects amplify the influence of the phonon scattering in the W doped MoSe₂, we investigate the phonon DOSs of the monolayer pristine MoSe₂ and Mo₀.₈₃W₀.₁₇Se₂ (figure 5(c)). We find that in the low-frequency range, the DOSs of the Mo₀.₈₃W₀.₁₇Se₂ is larger than those of the MoSe₂. Due to the correlation between the phonon DOSs and the defect-induced phonon scattering rate as shown in equations (2) and (3), the defect-induced phonon scatterings of the W doped MoSe₂ would have more impact on the thermal conductivity than that of the monolayer MoSe₂. In addition, we noticed that the Mo₀.₈₃W₀.₁₇Se₂ generates a new peak of DOSs at around 7.5 THz. However, this new peak of DOSs has a very limited contribution to the thermal conductivity because the group velocities of phonons around the 7.5 THz frequency are almost zero. Another explanation of how the introduced Se vacancies amplify the influence of the phonon scattering in W doped MoSe₂ is the mass difference between the W and Mo atoms. Since the mass of the W atom is larger than that of the Mo atom, the missing Se atom at a vacancy site results in a larger mass difference (compared to the average mass of the cell), which results in the larger kinetic energy and potential energy change. It enhances the defect-induced phonon scatterings and results in the further suppression of the thermal conductivity of the W doped MoSe₂.
Conclusion

In conclusion, we investigate the role of size, defects and W doping on thermal conductivity of monolayer MoSe$_2$ by the first principles calculation and the phonon Boltzmann transport equation. We find that 1%, 2% and 4% Se vacancies decrease the thermal conductivity of monolayer MoSe$_2$ of size 2 $\mu$m by 27.7%, 39.5% and 51.9%, respectively at the room temperature. However, 16.7% W doping could enhance the thermal transport of the monolayer MoSe$_2$ with 2% Se vacancy by 80% if all vacancies can be suppressed by W-doping, which could be explained by the fewer three-phonon scattering phase spaces of Mo$_{0.83}$W$_{0.17}$Se$_2$ and could also be supported by the larger gap between the optical and acoustic phonon branches in WSe$_2$ than that in MoSe$_2$. However, the W doping in the defective MoSe$_2$ amplifies the influence of the phonon scattering caused by the Se vacancies, which results in a further decrease in thermal conductivity due to the higher phonon DOSs of Mo$_{0.83}$W$_{0.17}$Se$_2$ and larger mass difference between W and Se atoms compared to Mo and Se atoms. Results indicate that for 16.7% W doping, the existence of 1%, and 2% Se vacancy concentration decreases the thermal conductivity of the monolayer MoSe$_2$ by 34.0%, and 46.2%, respectively, at the room temperature. The results from this work will help to understand the phonon transport properties of monolayer MoSe$_2$ under the influence of defects and doping, and provide insights for the future design of MoSe$_2$-based electronics.
